1 Introduction

It is quite common in data science to manipulate geographic data in the form of the geodetic coordinates (latitude, longitude) of locations on the globe. It often happens that one has a single geographic location S (the source) and a set of geographic locations \hat{T} (the targets) and would like to answer one of the following questions:

1. return the closest N targets in \hat{T} to S
2. return all targets in \hat{T} within a given distance d to S

One can solve this by computing the distance $d(t_i, S)$ from every target to the source but for sufficiently large \hat{T} this can be too slow for many purposes. A better solution is to make a bounding region \mathcal{B} around S and compute the distance $d(t_i, S)$ only for the $t_i \in \mathcal{B}$.

There are numerous ways to store a set of geographic locations in memory or on disk. For this bounding box algorithm useful one must utilize a fast method of filtering \hat{T} to those inside \mathcal{B} . We have provided a python library which does this.

Geographic locations are typically given in the longitude-latitude coordinate system, so \mathcal{B} should be constructed from lines of equal latitude and lines of equal longitude. This results in \mathcal{B} which look roughly square close to the equator and a sort of curved quadrilateral when near the poles and finally a semi-circle when the box touches a pole.

2 Constructing the Bounding Box

We denote by $C_{S,d}$ the equidistant surface around S , it is the collection of points on the sphere which are exactly at a distance d from S . The bounding box around $C_{S,d}$ should have the following properties:

1. $\mathcal{B} = \bigcup_i \mathcal{B}_i$ should consist of regions \mathcal{B}_i where each \mathcal{B}_i is enclosed by lines of constant latitude and lines of constant longitude
2. The equidistant surface $C_{S,d}$ should fit inside \mathcal{B} .

To construct the smallest bounding box \mathcal{B} which satisfies these points, we need to determine the minimum and maximum values of latitude and longitude attained by $C_{S,d}$. In practice we will utilize just two bounding regions \mathcal{B}_f and \mathcal{B}_r for the front and reverse sides of the sphere relative to S . It seems plausible that more compact \mathcal{B} could be constructed by considering \mathcal{B} with more than two regions.

2.1 Haversine Formula

Two common methods to compute distances on the sphere are the Haversine and Vincenty metrics. Both metrics use the geodetic coordinate system; the Haversine metric assumes the earth is exactly spherical while the Vincenty metric includes the oblateness of the earth. In this work we will use the Haversine formula as an approximation to the true distance between points.

The Haversine distance d between two points (φ_1, λ_1) and (φ_2, λ_2) is

$$\sin^2 \left(\frac{d}{2R} \right) = \sin^2 \left(\frac{\varphi_1 - \varphi_2}{2} \right) + \cos \varphi_1 \cos \varphi_2 \sin^2 \left(\frac{\lambda_1 - \lambda_2}{2} \right) \quad (1)$$

or more conveniently

$$\cos \frac{d}{R} = \sin \varphi_1 \sin \varphi_2 + \cos(\lambda_2 - \lambda_1) \cos \varphi_1 \cos \varphi_2. \quad (2)$$

where R is the radius of the sphere.

2.2 Maximum Latitude

The maximum latitude on $C_{S,d}$ is attained when the longitude is the same as the longitude of S . When two longitudes are equal

$$\lambda_2 = \lambda_1 \quad (3)$$

the Haversine formula gives

$$\varphi_2 - \varphi_1 = \frac{d}{R} \quad (4)$$

2.3 Maximum Longitude

2.3.1 Ellipse

To warm up to the computation of the point of maximum longitude, we first look at an ellipse in \mathbb{R}^2 :

$$a^2x^2 + b^2y^2 = 1 \quad (5)$$

and look for the extremum values of x .

We solve for x

$$x(y) = \frac{1}{a} \sqrt{(1 - b^2y^2)} \quad (6)$$

and compute the variation of x w.r.t. y

$$x'(y) = \frac{1}{a} \frac{2b^2y}{(1 - b^2y^2)} \quad (7)$$

The extremum of x are of course at the point where $x'(y) = 0$ and this is at $y = 0$, in particular on the x -axis. This gives two extremum:

$$x_{extr} = (\pm \frac{1}{a}, 0) \quad (8)$$

2.3.2 Back to the Sphere

Given a section $C_{S,d}$ of equal distance d from the source $S = (\varphi_1, \lambda_1)$ we want to know the maximum longitudinal distance, i.e. the maximum value of $|\lambda_2 - \lambda_1|$. These will be the east and west boundaries of the bounding box.

We first fix d and (φ_1, λ_1) then look for the extremum of λ_2 as a function of φ_2 . It is convenient to change coordinates to

$$\Lambda = \cos(\lambda_1 - \lambda_2(\varphi_2)), \quad \Psi = \sin \varphi_2 \quad (9)$$

then the equations to be solved are

$$\csc \varphi_1 \cos \frac{d}{R} = \cot \varphi_1 \Lambda \sqrt{1 - \Psi^2} + \Psi \quad (10)$$

$$\cot \varphi_1 \Lambda \Psi = \sqrt{1 - \Psi^2} \quad (11)$$

The solution is

$$\Lambda = \sec(\varphi_1) \sqrt{\cos^2\left(\frac{d}{R}\right) - \sin^2(\varphi_1)} \quad (12)$$

$$\Psi = \sec\left(\frac{d}{R}\right) \sin \varphi_1 \quad (13)$$

There is a branch point in Λ at one of the following points:

$$\text{b.p. } \varphi_1 \pm \frac{d}{R} = \pm \pi/2 \quad (14)$$

which is where the bounding section touches the north(south) pole. At this point the maximum longitude reached is $\lambda_2 - \lambda_1 = \pi/2$ which is half way around the globe (though not necessarily at the equator).

2.3.3 Equal Latitude

One can also consider a related but inequivalent question, which is to construct the shortest distance between two points of equal latitude. This is slightly non-trivial since the great circle between two points does not follow lines of equal latitude unless both points are on the equator. Indeed in this interesting blog post the author addresses the distinction between great circles and lines of constant latitude but mistakenly assumes that the maximum longitude is attained at a location with the same latitude as the source S .

To compute the distance between two points of equal latitude, we use the Haversine formula with

$$\varphi_1 = \varphi_2 = \varphi. \quad (15)$$

Then we find

$$d = 2R \sin^{-1} \left| \cos \varphi \sin \left(\frac{\lambda_1 - \lambda_2}{2} \right) \right| \quad (16)$$

$$\Rightarrow |\lambda_1 - \lambda_2| = 2 \left| \sin^{-1} \left[\frac{\sin \left(\frac{d}{2R} \right)}{\cos(\varphi)} \right] \right|. \quad (17)$$

3 Constructing the Bounding Box

3.1 Pole Inside Bounding Box

When the north or south pole is within a distance d from S , the naive bounding box will cross the pole and therefore occupy all values of longitude. We proceed by constructing two bounding boxes, \mathcal{B}_f (the *front*) for the longitude region of width π centered on S and another \mathcal{B}_r (the *reverse*) for the remaining π -sized region. When the pole is the north(south) pole, then the south(north) limit of \mathcal{B}_f is determined by the point on $C_{S,d}$ directly south(north) of S while the south(north) limit of the \mathcal{B}_r is determined by the intersection of $C_{S,d}$ with the constant longitude lines of \mathcal{B}_f . This is demonstrated in figure 1:

To construct \mathcal{B}_r we need to know the intersection of $C_{S,d}$ with the lines of longitude $\frac{\pi}{2}$ from S . In (2) we set $\lambda_2 - \lambda_1 = \frac{\pi}{2}$ and get

$$\sin \varphi_2 = \frac{\cos \frac{d}{R}}{\sin \varphi_1} \quad (18)$$

which gives the southern(northern) extremity of a \mathcal{B}_r which intersects the north(south) pole.

Figure 1: Construction of the two bounding boxes around S , where S is near a pole on the sphere. The bounding boxes are marked by dashed lines and appear as hemispheres. The equidistant surface is in red. The radial lines are at constant longitude, intersecting at the pole in the center of the figure.
